Supporting Information

ABSTRACT: Efficient unassisted solar water splitting, a pathway to storable renewable energy in the form of chemical bonds, requires optimization of a photoelectrochemical device based on photovoltaic tandem heterojunctions. We report a monolithic photocathode device architecture that exhibits significantly reduced surface reflectivity, minimizing parasitic light absorption and reflection losses. A tailored multifunctional crystalline titania interphase layer acts as a corrosion protection layer, with favorable band alignment between the semiconductor conduction band and the energy level for water reduction, facilitating electron transport at the cathode–electrolyte interface. It also provides a favorable substrate for adhesion of high-activity Rh catalyst nanoparticles. Under simulated AM 1.5G irradiation, solar-to-hydrogen efficiencies of 19.3 and 18.5% are obtained in acidic and neutral electrolytes, respectively. The system reaches a value of 0.85 of the theoretical limit for photoelectrochemical water splitting for the energy gap combination employed in the tandem-junction photoelectrode structure.

Electrochemical water splitting was achieved by van Troostwijk and Deiman in 1789 and, about a decade later, by Nicholsons and Carlisle,†,‡ whereas light-induced unassisted water splitting with rutile as a photoanode was reported in 1972, resulting in a small but measurable efficiency.† Efficient solar water splitting was first achieved using a dual-junction tandem photoelectrode under a light intensity equivalent to 11 suns.

In 2015, several devices with solar-to-hydrogen (STH) efficiency greater than 10% at 1 sun illumination were reported,‡ and in 2017, an efficiency of 16.2% was achieved.§ Overall, advances in solar water splitting have led to a number of functional prototypes of photoelectrochemical and photoelectrosynthetic cells in recent years,‡ featuring improved photoelectrode stability through the use of corrosion protection layers.¶ However, comparison of STH efficiencies realized so far with theoretical limiting efficiencies§ shows considerable room for further improvement; at present, the highest-efficiency systems reach about 2/3 of the theoretical limiting value for a given photoelectrode. To enable STH efficiencies approaching theoretical limits, the photovoltage has to be as large as possible, which requires a minimized photocurrent density. This in turn dictates that the charge carrier recombination at interfaces must be prevented. To maximize the photocurrent, a reduction of the photoelectrode surface reflectivity under operating conditions is also required, as is mitigation of light absorption in the catalyst layer applied to the photoelectrode surface.†

If one utilizes the band gap combination of a given tandem photoelectrode and the best reported exchange current densities for the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) and omits losses due to...
external radiative efficiency (ERE) defined as the portion of radiative recombination to the total (radiative and non-radiative) recombination and solution resistance, the realistic limiting STH efficiencies can be calculated. For the tandem photoelectrode used here (see Supporting Information section S1), this value is 22.8%. Approaching such limiting efficiencies provides a clear objective for a renewable fuels technology because inclusion of hydrogen in the existing worldwide fuel generation infrastructure could enable direct and widespread application of renewable fuels in the transportation sector and for electricity generation.

Here, we demonstrate an approach to achieving efficiencies near the theoretical limits for the photoelectrode energy band gaps employed. A key aspect of our approach is (i) the use of a crystalline anatase TiO2 photocathode interfacial layer (see Supporting Information section S3), deposited by atomic layer deposition (ALD), to facilitate reduced reflectivity and interface recombination velocity and (ii) a size distribution and spatial arrangement of Rh catalyst nanoparticles (NPs) tailored to achieve ultralow light attenuation. The crystalline anatase TiO2 interlayer shows excellent energy band alignment with the tandem window layer and its interfacial ultrathin oxidized surface part and with the electrolyte. In addition, it serves as an efficient antireflection coating and as a support for the catalyst NPs, with enhanced adhesion relative to III–V compound semiconductor surfaces.

We employ a dual-junction tandem photoelectrode where the high-band-gap subcell thickness has been increased for better current matching and the transparency of the tunnel diode was improved. To further increase the STH efficiency, interfacial layers have been designed to reduce charge carrier recombination and to increase optical light coupling into the photoelectrode absorber layers. The surface conditioning sequence resulted in etching of the GaAs cap layer by an NH4OH–H2O2–H2O solution, leaving an oxidized surface layer (AlInP0.2) on top of the n+-doped AlInP window layer (see Supporting Information section S1). A crystalline anatase TiO2 film with an effective thickness of 30 nm was deposited to act as a corrosion protection layer and an antireflection coating, as well as serving as a conducting substrate surface for photoelectrodeposition of Rh NP electrocatalysts. The Rh NPs exhibited large surface areas and thus high exchange current and, simultaneously, particularly low light attenuation. The photocathode device configuration employed is generally less prone to photodecomposition than photoanode devices, where charge carriers with high oxidation potential are present at the semiconductor surface. Figure 1 shows a schematic of the resulting device: the photoelectrode consisting of GaInP and GaInAs subcells on a GaAs substrate, an anatase TiO2 protective layer, the Rh NP catalyst layer, and a sputtered RuO2 counter electrode (OER) are depicted. Also depicted on the side of the layer structure in Figure 1 is an energy band diagram under illumination where the quasi-Fermi levels show the splitting for electrons and holes necessary to achieve unassisted water splitting (see Supporting Information section S4). The surface of the crystalline TiO2 film illustrated in Figure 1b indicates a continuous film with height variations, seen by AFM, that give it a flake-like appearance. Figure 1c illustrates the protocol for pulsed photoelectrodeposition of Rh catalyst NPs (see Supporting Information section S1), and the inset gives SEM and AFM images of the Rh NPs. Figure 1c depicts the procedure to obtain the highest-activity catalysts at almost negligible light attenuation; fine control of particle size smaller than 20 nm was achieved by careful adjustment of the electrode potential, enabling considerably higher catalyst loading compared to that of a dense film of equivalent catalyst loading deposited by conventional vapor-phase or electrochemical reduction. This procedure facilitates photocathodes with high-transparency catalysts, which maintain high photocurrent densities and result in increased efficiency, which is determined from the relation

$$\eta_{\text{STH}} = \frac{J_{\text{op}} - E_{\text{em}} J_{\text{FE}}}{P_{\text{in}}}$$  \hspace{1cm} (1)$$

The solar fuel generator efficiency $\eta_{\text{STH}}$ is given by the operating current at the counter electrode potential, the thermodynamic value for the reaction ($E_{\text{em}} = 1.23$ V for water splitting under standard conditions), and the reaction Faradaic
efficiency $f_{Phil}$ determined by gas product analysis measurements.

electronically, the photoelectrode configuration used here facilitates alignment of the conduction bands of the AlInP window layer of the tandem photoelectrode to the indium oxide and indium phosphate layers (created by the cap layer etching process) and the anatase TiO$_2$ protection/antireflective layer. We note that photogenerated electrons, which are minority carriers in the main part of the tandem subcells, become majority carriers in the AlInP and TiO$_2$ layers, reducing recombination losses in carrier transport. Details of the energy band alignment and the photoelectron spectroscopy and optical data used to support it are described in the Supporting Information section S4. In addition, the large valence band offset between AlInP and TiO$_2$ blocks interfacial hole transport, resulting in a small overall reverse saturation current, improving the photovoltage. This feature is important for achieving high STH efficiencies.

The influence of the surface modifications on optical properties and on the photocurrent is shown in Figure 2. A reduction of the reflectivity by $\sim$15% is achieved by use of the TiO$_2$ interlayer (Supporting Information section S5), whereas...
the Rh NPs in Figure 2a show negligible additional absorption, which is attributed to the blue-shifted plasmonic resonance of the Rh NPs. For particle sizes below 20 nm, a shift from the visible region into the ultraviolet one occurs, making the Rh layer almost fully transparent.\textsuperscript{14–16} The detailed optimization of the optical design regarding the thickness of TiO$_2$ and Rh particle size is discussed in Supporting Information section S6 including both simulations and experimental support.

The corresponding photocurrent—voltage characteristics in an acidic electrolyte demonstrate a pronounced increase in the current and, as expected, also a shift of the bend of the photocurrent characteristic toward more anodic potentials, thereby additionally increasing the photocurrent at the RuO$_2$ counter electrode (OER) potential. The result with incorporation of TiO$_2$ is a relative increase of 28% of the tandem cell output. A STH efficiency of 19.3% is obtained at 0 V, with an operating current of 15.7 mA/cm$^2$, assuming an initial Faradaic efficiency of unity, which is supported by the gas evolution measurements shown in Figure 3b. These data represent a 20% increase in efficiency above the previously reported 1 sun photoelectrosynthetic cell efficiency benchmark.\textsuperscript{5}

The high photocurrent at 0 V vs RuO$_2$ indicates that electron transport is virtually uninhibited from the absorber layer through the indium and phosphorus oxide and TiO$_2$ electron transport is virtually uninhibited from the absorber thereby additionally increasing the photocurrent at the RuO$_2$ photocurrent characteristic toward more anodic potentials, and, as expected, also a shift of the bend of the current and, as expected, also a shift of the bend of the corresponding $J−V$ curve is shifted to cathodic potentials. However, device operation at pH 7 still yields a high STH efficiency of 18.5% and the device appears to be stable for a more extended period, in accordance with predictions of TiO$_2$ stability from thermodynamics. Even a slower reduction of the photocurrent is observed; we found that this photocurrent reduction could be partially reversed by immersion of the device from the electrolyte solution and applying a soft cleansing procedure (see Supporting Information section S8). The observation that the photocurrent can be partially restored appears to rule out loss of Rh catalyst particles or even partial removal of the anatase interfacial layer as causes of photocurrent reduction. We find, however, that the surface chemistry of Rh is influenced by the phosphate buffer of the neutral electrolyte; XPS in Supporting Information section S10 clearly indicates PO$_4$ formation on the Rh surfaces because of the absence of an In signal, which would have been observed in case of InPO$_4$ formation, concurrent with corrosion of the absorber. The photovoltaic regeneration procedure results in a 50% recovery of the photocurrent lost during the first 12 h, suggesting that the high porosity of the Rh NP layer inhibits full recovery by short intermediate treatment. Employing a different electrolyte for pH 7 conditions might therefore benefit long-term activity of the device. (see details in Supporting Information section S10).

Increasing the efficiency of a photoelectrosynthetic device from already high values toward theoretical limits is especially challenging. We have used a series of surface conditioning steps that have a two-fold function: light management was drastically improved and the electronic properties were at least maintained. Compared to our earlier results,\textsuperscript{5} we see an increase in the available cell voltage that is related to the increase in photocurrent at the counter electrode operation potential. Junction formation between the etched AlInP layer, TiO$_2$ layer, and Rh NPs suggests that the Fermi level alignment is nearly ideal.

Figure 4 shows a summary to date of selected STH efficiencies realized for monolithic integrated photoelectrosynthetic devices capable of unassisted water splitting.

Using the parameters shown in Table 1, our photoelectrosynthetic device reaches 0.85 of the theoretical limiting efficiency. It should be noted that the theoretical efficiency
determined from the data in Table 1 is based on the best presently known electrocatalysts, a unity photoelectrode radiative efficiency, and an absence of absorption losses.9 We also calculated the STH efficiency as a function of Tafel slope, exchange current density, and ohmic drop to evaluate whether the optical or the electrochemical polarization losses dominate the solar cell performance (see Supporting Information section S7, Figure S17). Our record device is located in the region of highest efficiency, showing that the optical loss is the limiting factor. However, the system, in principle, reacts sensitively to the polarization losses, emphasizing the importance of judiciously combining the interface and catalyst.

Stability appears to remain an issue of this photocathode device configuration, but we have demonstrated high efficiency in neutral electrolytes and that extended operation of photocathode devices becomes possible if one can control the Rh surface chemistry. The use of Rh NPs with tailored size and shape distributions enables ultralow absorption. The future design of even more optimized tandem photoelectrodes appears to be possible, enabling solar fuel generation (water splitting as well as CO2 or N2 reduction) efficiencies to be even higher than those reported here, for example, with STH champion device efficiencies of >20% for integrated direct water photolysis being a realistic goal.
